

Renal Dysfunction Is Associated With Poststroke Discharge Disposition and In-Hospital Mortality

Findings From Get With The Guidelines–Stroke

Background and Purpose—Kidney disease is a frequent comorbidity in patients presenting with acute ischemic stroke. We evaluated whether the estimated glomerular filtration rate (eGFR) on admission is associated with poststroke in-hospital mortality or discharge disposition.

Methods—In this cohort study, data from ischemic stroke patients in Get With The Guidelines–Stroke linked to fee-for-service Medicare data were analyzed. The Modification of Diet in Renal Disease study equation was used to calculate the eGFR (mL/min/1.73 m²). Dialysis was identified by *International Classification of Diseases, Ninth Revision* codes. Adjusted multivariable Cox proportional hazards models were used to determine the independent associations of eGFR with discharge disposition and in-hospital mortality. Adjusted individual models also examined whether the association of clinical and demographic factors with outcomes varied by eGFR level.

Results—Of 232 236 patients, 47.3% had an eGFR \geq 60, 26.6% an eGFR 45 to 59, 16.8% an eGFR 30 to 44, 5.6% an eGFR 15 to 29, 0.7% an eGFR <15 without dialysis, and 2.8% were receiving dialysis. Of the total cohort, 11.8% died during the hospitalization or were discharged to hospice, and 38.6% were discharged home. After adjusting for other relevant variables, renal dysfunction was independently associated with an increased risk of in-hospital mortality that was highest among those with eGFR <15 without dialysis (odds ratio, 2.52; 95% confidence interval, 2.07–3.07). An eGFR 15 to 29 (odds ratio, 0.82; 95% confidence interval, 0.78–0.87), eGFR <15 (odds ratio, 0.72; 95% confidence interval, 0.61–0.86), and dialysis (odds ratio, 0.86; 95% confidence interval, 0.79–0.94) remained associated with lower odds of being discharged home. In addition, the associations of several clinical and demographic factors with outcomes varied by eGFR level.

Conclusions—eGFR on admission is an important predictor of poststroke short-term outcomes. (*Stroke*. 2017;48:327-334. DOI: 10.1161/STROKEAHA.116.014601.)

Key Words: acute kidney injury ■ glomerular filtration rate ■ kidney disease ■ Medicare ■ outcomes ■ stroke

Renal disease is prevalent among stroke patients and is associated with worse stroke outcomes.^{1–3} Elevated estimated glomerular filtration rate (eGFR) on admission for stroke may reflect acute kidney injury or chronic kidney disease (CKD), which may in turn worsen the outcome after acute stroke. Data on the association of eGFR on admission with poststroke outcomes is inconsistent. For example, in one study, an eGFR of 15 to 44 during hospitalization for acute stroke was associated with increased 1-year mortality.⁴ Several other studies, however, find that proteinuria rather than eGFR was associated

with in-hospital mortality.^{3,5} These studies were limited by the way eGFR was categorized, and patients on dialysis were not analyzed separately. Furthermore, it is uncertain whether the effect of patient or hospital-level characteristics on poststroke outcomes varies by the level of kidney dysfunction.

Understanding the impact of admission eGFR on short-term outcomes and its interaction with clinical and demographic factors is important as it may inform targeted interventions for high-risk patients. Addressing this gap is also important to properly adjust for case mix in outcome studies and payment models.

The objectives of this study were to (1) examine the independent associations of the different levels of renal dysfunction, including being on dialysis, with discharge disposition and in-hospital mortality in a large Get With The Guidelines (GWTG)–Stroke cohort of patients who were eligible for fee-for-service Medicare at the time of the index acute ischemic stroke admission and (2) assess the relationships of patient and hospital characteristics with short-term outcomes (discharge home, inpatient mortality) stratified by eGFR levels.

Methods

Patient Population

We used data on patients admitted with ischemic stroke between 2009 and 2012 from fully participating sites from the GWTG–Stroke program database that was linked to Centers for Medicare and Medicaid Services (CMS) claims data. Details of the GWTG–Stroke program have been previously published.^{1,6} GWTG is a voluntary, national, quality-improvement initiative sponsored by the American Heart Association and American Stroke Association designed to improve adherence to the guideline-based care of patients hospitalized with stroke and transient ischemic attack. GWTG–Stroke participating hospitals record data from all stroke and TIA admissions. Case ascertainment is based on clinical identification during the hospitalization, retrospective surveillance of *International Classification of Diseases, Ninth Revision* (ICD-9) codes, or both. Trained personnel extract data on demographics, medical history, in-hospital treatment, and discharge characteristics.⁶ Quintiles Real-World & Late Phase Research (Cambridge, MA) serves as the data collection and coordination center for GWTG. The Duke Clinical Research Institute (Durham, NC) serves as the data analysis center.^{1,6} Institutional review board approval was obtained for this study.

A total of 341 602 patients from 1679 GWTG–Stroke fully participating sites who were admitted between 2009 and October 2014 and who had records linked to CMS claims data were identified. From this cohort, 603 had missing race information; 59 378 patients had missing serum creatinine (Cr); 1471 had Cr <0.5 mg/dL and 856 had Cr >15 mg/dL (these values were considered less likely to be physiological); 13 650 were not eligible for fee-for-service Medicare at time of index stroke hospitalization admission and discharge; 27 935 were transfer inpatients or patients who received intravenous tissue-type plasminogen activator at an outside hospital; and 5473 had discharge status missing, left against medical advice, not documented or unable to determine, or were transferred to another acute care facility. The remaining 232 236 patients with ischemic stroke aged ≥65 years who were admitted from 1581 sites were included in the analysis.

Variables

Renal Dysfunction Definitions

eGFR was estimated based on the Modification of Diet in Renal Disease equation ($eGFR = 175 \times \text{serum creatinine}^{-1.154} \times \text{age}^{-0.203} \times [1.210 \text{ if race=black}] \times [0.742 \text{ if sex=female}]$) using creatinine on admission.⁷ The eGFR groups were mutually exclusive. Dialysis patients were identified based on ICD-9 codes, and the remaining groups were defined based on calculated eGFRs.

The eGFR levels were selected based on CKD classification by the National Kidney Foundation–Kidney Disease Outcomes Quality Initiative: eGFR 45 to 59 mL/min/1.73 m² (CKD stage 3a); eGFR 30 to 44 mL/min/1.73 m² (CKD stage 3b); eGFR 15 to 29 mL/min/1.73 m² (CKD stage 4); eGFR <15 mL/min/1.73 m² without dialysis (CKD stage 5 without dialysis); and treatment by dialysis. In this study, eGFR ≥60 mL/min/1.73 m² was categorized as no kidney dysfunction. Because the definition of CKD requires longitudinal eGFR data for at least 3 months and because follow-up eGFR was not available, the data were analyzed by eGFR level rather than CKD stage.

To further study the association of renal dialysis with outcomes, patients receiving dialysis were analyzed separately from those not receiving dialysis who had an eGFR <15 mL/min/1.73 m². Because

dialysis status was not available in GWTG data, the GWTG database was linked with CMS data with dialysis patients identified by ICD-9 diagnosis codes V45.11 (renal dialysis status), 585.6 (end-stage renal diseases), V56.X (encounter for dialysis and dialysis catheter care).

Outcomes

In-hospital mortality included any death before discharge or being discharged to hospice. Discharge disposition was dichotomized into discharge home versus other.

Covariates

The covariates for the adjusted analysis of the association of admission eGFR with inpatient mortality/hospice and discharge disposition included the standard GWTG–Stroke adjustment variable list: (1) demographics: age, sex, and race; (2) medical history: atrial fibrillation/flutter, previous stroke/TIA, coronary artery disease/previous myocardial infarction (MI), carotid stenosis, diabetes mellitus, peripheral vascular disease, hypertension, dyslipidemia, and smoking; (3) other patient characteristics: arrival on versus off hours, initial National Institutes of Health Stroke Scale (NIHSS) score; (4) hospital characteristics such as region, hospital type (teaching/nonteaching), number of beds, annual ischemic stroke volume, annual intravenous tissue-type plasminogen activator volume, rural location, and Joint Commission primary stroke center status.

The variables that were included in the interaction analysis with admission eGFR were selected a priori based on their possible association with stroke outcomes and included, in addition to the above variables, initial systolic blood pressure, glucose level, low-density lipoprotein cholesterol, and independent ambulatory status at admission. For each variable of interest, individual models for each eGFR stage were created with the standard GWTG–Stroke adjustment variable list.

Statistical Analysis

Patient and hospital characteristics were summarized and compared by eGFR groups and dialysis status using proportions for categorical variables and medians with 25th and 75th percentiles for continuous variables. Differences were compared using Pearson χ^2 tests, Fisher Exact Test, or Kruskal–Wallis tests as appropriate.

The relationship between eGFR groups and patient outcomes were quantified using multivariable logistic regression with generalized estimating equations. Generalized estimating equation methods were used to account for potential correlation and clustering of patients within hospitals. Results are reported as odds ratios (ORs) with 95% confidence intervals (CIs) with the eGFR ≥60 group as reference.

To assess whether eGFR levels interacted with patient and hospital factors, adjusted and unadjusted logistic regression models with GEE were run for each factor of interest. Adjustment variables were based on the standard GWTG–Stroke list (described under covariates). For each factor, we report the interaction *P* value; a significant interaction ($P < 0.05$) suggests that eGFR level modifies the relationship between the factor and outcome. In such situations, the OR and 95% CI between the factor and outcome is provided for each eGFR category.

Lack-of-fit tests were used to compare linear fit and nonlinear fit models. If nonlinearity was found, appropriate transformations were used to achieve linearity. Linear splines were used for glucose (knots at 100 and 150 mg/dL), low-density lipoprotein (knot at 65 mg/dL), and systolic blood pressure (knot at 150 mm Hg) in the in-hospital mortality/hospice model. In addition to these variables, linear splines for hospital size (knot at 250 beds) and annual intravenous tissue-type plasminogen activator volume (knot at 15) were used in the discharged home model. Colinearity between covariates was assessed using variance inflation factors. Large variance inflation factor values (variance inflation factor >5) between variables were examined. If there was evidence of strong correlation between 2 covariates, 1 was excluded from the model.

Multiple imputations with 25 imputations was used to estimate missing data in the models. If a patient had missing medical history, it was assumed that the medical conditions did not occur as abstractors were likely to skip the section when none applied. Hospital characteristics were not imputed.

Percentages are based on nonmissing data. BMI indicates body mass index; CAD, coronary artery disease; EMS, emergency medical services; INR, international normalized ratio; IV, intravenous; MI, myocardial infarction; NIHSS, National Institutes of Health Stroke Scale; r-tPA, recombinant tissue-type plasminogen activator; TIA, transient ischemic attack; and tPA, tissue-type plasminogen activator.

Sensitivity Analysis

Because admission eGFR may reflect acute renal dysfunction and not always reflect CKD, sensitivity analyses were performed to examine

the association of outcomes and patient and hospital factors classified by eGFR but confined to patients who also have ICD-9–Clinical Modification (CM) codes reflecting CKD. CKD was identified by

the following codes: 585.3 (CKD stage 3), 585.4 (CKD stage 4), 585.5 (CKD stage 5 excluding patients requiring chronic dialysis), 585.6 (end-stage renal disease requiring chronic dialysis), and 585.9 (CKD unknown/unspecified).

Results

Of 232236 patients with ischemic stroke, aged ≥ 65 years, 109913 (47.3%) had an eGFR ≥ 60 ; 61719 (26.6%) an eGFR 45 to 59; 39201 (16.8%) an eGFR 30 to 44; 13118 (5.6%) an eGFR 15 to 29; 1700 (0.7%) an eGFR <15 without dialysis, and 6585 (2.8%) patients were receiving dialysis. Characteristics of the cohort and hospital characteristics by eGFR levels are described in Table 1 and Table I in the [online-only Data Supplement](#), respectively. The median age of the cohort was 81 years (25th–75th percentile: 74–87 years). Compared with subjects with eGFR ≥ 60 years (median age: 78 years; 25th–75th percentile: 71–85 years), those with eGFR <60 were older, except for those on dialysis (median age 76 years; 25th–75th percentile: 70–82 years). About 59% of the entire cohort were women, and 80% were white. There were fewer whites (58.1%) and more blacks (27.6%) among those on dialysis compared with the other groups. History of stroke/TIA, coronary artery disease/myocardial infarction, carotid stenosis, diabetes mellitus, peripheral vascular disease, hypertension, dyslipidemia, and heart failure were more common in those on dialysis; patients on dialysis were more likely to be taking antiplatelet or anticoagulant drugs, anti-hypertensive medications, lipid-lowering medications, and diabetic medications before admission. The highest median NIHSS was among those with eGFR <15 without dialysis (NIHSS=8; 25th–75th percentile: 3–17). The percentage of receiving intravenous tissue-type plasminogen activator was lowest among those with GFR <15 not on dialysis.

In-Hospital Mortality or Hospice

Of the total cohort, 27409 (11.8%) died in the hospital or were discharged to hospice. Inpatient mortality or discharge to hospice was most common in those with an eGFR <15 without dialysis (n=497; 29.2%) and least common among those with eGFR ≥ 60 (n=10054; 9.1%). In-hospital mortality or discharge to hospice occurred in 12.1% (n=7512) of patients with an eGFR 45 to 59, 14.8% (n=5807) with an eGFR 30 to 44, 20.3% with an eGFR 15 to 29 (n=2664), and 13.2% (n=875) with patients on dialysis. After adjusting for other relevant variables, when compared with those with GFR ≥ 60 , all other

eGFR levels were independently associated with increased odds of in-hospital mortality or discharge to hospice, with the highest risk among those with GFR <15 without dialysis (eGFR <15 versus eGFR >60 ; OR, 2.52; 95% CI, 2.07–3.07; $P<0.0001$; Table 2).

Discharge Disposition

Of the total cohort, 89696 (38.6%) were discharged home. Discharge home was most common among those with an eGFR ≥ 60 (n=47051; 42.8% of those with eGFR ≥ 60) and least common in those with an eGFR <15 without dialysis (N=400; 23.5% of those with eGFR <15 without dialysis). The frequency of discharge home was 37.3% in those with an eGFR 45 to 59 (n=23037), 33.6% with an eGFR 30 to 44 (n=13185), 27.5% with an eGFR 15 to 29 (n=3617), and 36.5% in those receiving dialysis (n=2406). After adjusting for other relevant variables, advanced kidney dysfunction including having an eGFR 15 to 29, eGFR <15 without dialysis, and dialysis were each associated with a lower odds of being discharged home, with the greatest association in those with eGFR <15 without dialysis (eGFR <15 versus eGFR >60 ; OR, 0.72; 95% CI, 0.61–0.86; $P=0.0002$; Table 3).

Association of Clinical and Demographic Factors With In-Hospital Mortality by eGFR Level

After covariate adjustment, the associations of age, previous stroke/TIA, systolic blood pressure on admission, glucose on admission, NIHSS, and teaching versus nonteaching hospital with in-hospital mortality varied by eGFR level (Table II in the [online-only Data Supplement](#)). For example, the interaction between eGFR and glucose level on admission was significant but was only reflected by a decreased odds of in-hospital mortality/hospice per 5 mg/dL increase of glucose in patients on dialysis who presented with a blood glucose ≤ 100 mg/dL (OR, 0.88; 95% CI, 0.82–0.94; $P=0.0003$). An increase in NIHSS was associated with a worse outcome across all GFR levels, but the association was highest among those with an eGFR ≥ 60 (OR, 1.99; 95% CI, 1.96–2.03; $P<0.0001$) and lowest in those with an eGFR <15 without dialysis (OR, 1.70; 95% CI, 1.54–1.87; $P<0.0001$). Being treated at a teaching versus nonteaching hospital was associated with decreased mortality/hospice only in those on dialysis (OR, 0.77; 95% CI, 0.61–0.97; $P=0.0265$). No interaction was found with history of atrial fibrillation.

Table 2. Association of eGFR Level and In-Hospital Mortality or Hospice for Patients Admitted With Ischemic Stroke

CKD Group (Reference=eGFR ≥ 60)	Unadjusted Odds Ratio (95% CI)	P Value	Global P	Adjusted Odds Ratio (95% CI)	P Value	Global P
eGFR 45–59	1.38 (1.34–1.43)	<0.0001	<0.0001	1.06 (1.01–1.10)	0.0162	<0.0001
eGFR 30–44	1.74 (1.68–1.80)	<0.0001		1.23 (1.17–1.29)	<0.0001	
eGFR 15–29	2.56 (2.44–2.67)	<0.0001		1.71 (1.58–1.85)	<0.0001	
eGFR <15	4.09 (3.66–4.56)	<0.0001		2.52 (2.07–3.07)	<0.0001	
Dialysis	1.54 (1.43–1.67)	<0.0001		1.56 (1.39–1.76)	<0.0001	

Reference group is eGFR ≥ 60 mL/min/1.73 m². CI indicates confidence interval; CKD, chronic kidney disease; and eGFR, estimated glomerular filtration rate.

Table 3. Association of eGFR Level and Discharge Home for Patients Admitted With Ischemic Stroke

eGFR Group (Reference=eGFR ≥60)	Unadjusted Odds Ratio (95% CI)	P Value	Global P	Adjusted Odds Ratio (95% CI)	P Value	Global P
eGFR 45–59	0.80 (0.780–0.82)	<0.0001	<0.0001	1.04 (1.01–1.07)	0.0065	<0.0001
eGFR 30–44	0.68 (0.66–0.70)	<0.0001		0.98 (0.94–1.01)	0.2302	
eGFR 15–29	0.51 (0.49–0.53)	<0.0001		0.82 (0.78–0.87)	<0.0001	
eGFR <15	0.42 (0.37–0.47)	<0.0001		0.72 (0.61–0.86)	0.0002	
Dialysis	0.78 (0.74–0.82)	<0.0001		0.86 (0.79–0.94)	0.0005	

Reference group is eGFR ≥60 mL/min/1.73 m². CI indicates confidence interval; and eGFR, estimated glomerular filtration rate.

Adjusted sensitivity analysis restricted to patients who had CKD identified by ICD-9-CM codes revealed that only the associations of sex and dyslipidemia with outcome varied by eGFR levels. Women were less likely to die in the hospital if they had eGFR 15 to 29 (OR, 0.79; 95% CI, 0.66–0.94; $P=0.0096$) and eGFR <15 without dialysis (OR, 0.56; 95% CI, 0.32–0.97; $P=0.0387$), whereas the association was not significant for other eGFR levels. Medical history of dyslipidemia was only associated with in-hospital mortality among those with an eGFR 30 to 44 (OR, 0.73; 95% CI, 0.64–0.83; $P<0.0001$).

Association of Demographic and Clinical Factors With Discharge Home by eGFR Level

After covariate adjustment, the association of age, sex, race, history of hypertension, history of dyslipidemia, NIHSS, and independent ambulatory status on admission with discharge home varied by eGFR levels (Table III in the [online-only Data Supplement](#)). For example, NIHSS was inversely associated with discharge home among those with eGFR ≥60 (OR, 0.42; 95% CI, 0.41–0.43; $P<0.0001$) and in those with kidney dysfunction but had the lowest effect size among those on dialysis (OR, 0.51; 95% CI, 0.47–0.56; $P<0.0001$). Independent ambulatory status on admission was associated with discharge home in those with eGFR ≥60 (OR, 3.33; 95% CI, 3.17–3.51; $P<0.0001$) as well as those with kidney dysfunction but the effect size was lowest in those on dialysis (OR, 2.66; 95% CI, 2.19–3.23; $P<0.0001$).

Adjusted sensitivity analysis restricted to those who also had an ICD-9-CM code consistent with CKD revealed that only the association of sex and hospital location (rural versus urban) with discharge home varied by eGFR level. Women were less likely to be discharged home if they had eGFR 45 to 59 (OR, 0.74; 95% CI, 0.65–0.84; $P<0.0001$), eGFR 30 to 44 (OR, 0.86; 95% CI, 0.78–0.94; $P=0.001$) or eGFR 15 to 29 (OR, 0.72; 95% CI, 0.63–0.82; $P<0.0001$), but the association was not significant for other eGFR levels. Being treated in a rural versus urban location increased the odds of discharge home if eGFR was 45 to 59 (OR, 1.35; 95% CI, 1.03–1.77; $P=0.0291$) and dialysis (OR, 1.79; 95% CI, 1.06–3.03; $P=0.030$) but was not significant in other eGFR levels.

Discussion

In this large nationwide study of Medicare beneficiaries aged ≥65 years with acute ischemic stroke and after adjusting for relevant clinical and demographic factors, eGFR on admission was a strong predictor of outcome and modified the

relationship of other clinical and demographic factors with in-hospital mortality and discharge disposition. Regardless of the eGFR level, patients with eGFR <60 were more likely to die in the hospital. In-hospital mortality after acute ischemic stroke was highest among patients with eGFR <15 without dialysis with about 2.5 times higher odds than those with eGFR ≥60 after adjusting for relevant variables. Patients with eGFR <15 without dialysis were also the least likely to be discharged home compared with those with eGFR ≥60. Compared with those with eGFR ≥60, patients with eGFR <15 without dialysis did worse than those on dialysis, either reflecting a beneficial effect of dialysis in patients with end-stage renal disease on stroke outcomes or potentially reflecting the underlying severity of the comorbidities in this group that may have precluded eligibility for dialysis. Those with eGFR <15 not on dialysis tended to have more severe strokes. In our study, we adjusted for comorbidities and NIHSS, and despite this, those with eGFR <15 still fared poorly, likely from underlying unmeasured confounders related to their vascular risk factors and poor health status at baseline.

Previous reports evaluating the association of renal dysfunction on admission with acute poststroke outcomes were inconsistent. For example, 2 studies found an association between in-hospital mortality and proteinuria, but no association with admission eGFR.^{3,5} One of these studies also did not find an association between the admission GFR and discharge home.⁵ The lack of association between admission GFR and poststroke outcomes in these studies could be because of the way GFR was categorized (classified into 3 groups in the one study and dichotomized as GFR ≥60 or <60 in the other). In addition, one of the studies excluded patients with known CKD.⁵ In contrast, GFR on admission independently predicted in-hospital mortality after acute myocardial infarction.⁸ CKD defined by ICD-9-CM codes was associated in one study with in-hospital mortality.⁹ The eGFR cutoffs in our study may better reflect the underlying severity of renal dysfunction. We also separately analyzed patients using dialysis in contrast to previous studies.¹ In addition, because of the large sample, we were able to adjust for multiple relevant covariates.

We also evaluated the interaction between renal dysfunction and patient- and hospital-level characteristics that may affect poststroke outcomes. We found that the association with outcomes of several patient- and hospital-level characteristics varied by eGFR level. For example, the association of sex with inpatient mortality varied by eGFR level only when the analysis was restricted to those who also had an ICD-9 diagnosis of

CKD. In this group, women were $\approx 20\%$ less likely than men to die in the hospital if the eGFR was 15 to 29 and 45% less likely if eGFR was <15 without dialysis, but there was otherwise no difference in in-hospital mortality between women and men. These results are consistent with previous findings of slightly lower mortality in women compared with men with CKD.¹⁰ Also, lower poststroke mortality was noted in women aged 35 to 54 years compared with men.¹¹ In contrast, another study found that in-hospital mortality in women with CKD hospitalized for stroke was higher compared with men, but a test for interaction with different levels of renal dysfunction was not performed.¹²

The association of sex with discharge disposition also varied by eGFR level. Women were as likely as men to be discharged home only if they had an eGFR <15 or were on dialysis but were otherwise less likely to be discharged home. This may be because eGFR <15 and dialysis are strong predictors of discharge outcomes, thus reducing the association with sex. These findings are consistent with previous studies that found an association between sex and poststroke outcomes. In one study, older women had a higher risk than men of poor functional outcome at discharge after acute ischemic stroke.¹³

The presence of advanced renal dysfunction reduced the associations of several demographic/clinical factors with outcomes. The associations of increased age, systolic blood pressure on admission, and initial NIHSS score were reduced in the setting of advanced renal dysfunction. In contrast, glucose on admission was associated with outcome only in patients receiving dialysis. Mortality decreased for each 5 mg/dL increase in glucose in patients receiving dialysis who presented with blood glucose ≤ 100 mg/dL, suggesting that hypoglycemia may play an even greater role in in-hospital mortality in dialysis patients. Interestingly, being treated at a teaching hospital was associated with lower mortality only in those on dialysis, possibly owing to the more complex care of these patients.

Similar patterns were found with factors associated with discharge home. Increased age played a smaller role in the association with discharge disposition among patients on dialysis compared with those not on dialysis. Admission NIHSS score and independent ambulatory status on admission were associated with outcome in all groups of patients including those with and without kidney dysfunction, but the effect size was lowest in those receiving dialysis.

Fewer interactions between eGFR and demographic and clinical factors were noted when restricting the analysis to those who also had ICD-9 indicating CKD. This may be because CKD ICD-9 codes may be insensitive and underestimated the prevalence of CKD.¹⁴ Alternatively, the interaction of GFR on admission, which could reflect acute renal impairment but not chronic renal disease, with clinical and demographic factors may be different in those who already have established CKD.

This study has limitations. The data are limited to GWTG-Stroke participating hospitals, and the Medicare population (aged ≥ 65 years) and may not be generalizable to a younger population. GWTG-Stroke hospitals do tend to be larger, urban, and teaching centers. GWTG-Stroke registry data, however, are generally representative of national fee-for-service Medicare ischemic stroke populations.¹⁵ In addition, the majority of individuals ≥ 65 years use Medicare in the

United States.¹⁶ Although generally valid, dialysis was identified based on ICD-9-CM codes, which may underestimate its true prevalence.¹⁷ Residual measures and unmeasured confounding cannot be excluded. Admission creatinine was not uniformly obtained introducing a possible selection bias. The Modification of Diet in Renal Disease formula used for the analysis may not be an entirely accurate measure of eGFR in the setting of acute ischemic stroke. Multiple testing was done in a large database that may increase the likelihood of finding statistically significant results by chance. Also, because of the large sample size, differences that are not clinically important may be statistically significant.

Among Medicare beneficiaries with acute ischemic stroke, in-hospital mortality increased across all levels of renal dysfunction and was highest in those with an eGFR <15 not receiving dialysis. Discharge home was less frequent in those with advanced renal dysfunction. The association of other factors with outcomes varied by the level of renal dysfunction, confirming that admission eGFR identifies a group of patients at risk for poor outcome.

Sources of Funding

The Get With The Guidelines (GWTG)–Stroke program is supported in part by a charitable contribution from Bristol-Myers Squibb/Sanofi Pharmaceutical Partnership and the American Heart Association Pharmaceutical Roundtable. GWTG-Stroke has been funded in the past through support from Boehringer-Ingelheim and Merck. This work was supported by the National Institute of Diabetes and Digestive and Kidney Diseases (P30DK096493).

Disclosures

Dr El Husseini received research support from the Mini Grant award from the Duke O'Brien Center for Kidney Research. The Mini Grant award is a subaward under Duke University's primary award from the National Institutes of Health (NIH), award number 1P30DK096493–01. Dr Fonarow receives other research support from the Patient Centered Outcome Research Institute, NIH/AHRQ, Get With The Guidelines (GWTG) Steering Committee, and is an employee of University of California which has a patent on an endovascular device. Dr Smith is a member of the American Heart Association–GWTG Steering Committee. Dr Hernandez receives other research support from Genentech, Daichi, Janssen, and AstraZeneca. Honoraria include AstraZeneca, Bayer and, and Novartis. The other authors report no conflicts.
